Abstract

We perform a renormalisation group analysis of the next-to-minimal supersymmetric standard model (NMSSM) based on the following constraints: two-loop gauge coupling unification at a variable scale M_X , running the gauge couplings through the low energy thresholds; universal soft supersymmetry breaking parameters; correct electroweak symmetry breaking. The phenomenological implications of our results include a standard model-like

Higgs boson of mass in the range 70-140 GeV.

Supersymmetry (SUSY) [1] is an attractive candidate for new physics beyond the standard model at the TeV scale. The existence of SUSY would greatly ease the naturalness problems associated with the construction of a grand unified theory (GUT) of the strong and electroweak interactions. The basic idea of GUTs is that the gauge couplings, which govern the strength of the strong and electroweak interactions at low energy, are actually equal to some unified coupling g_X at some very high scale M_X due to their renormalisation group (RG) running [2]. The original motivation for SUSY broken at a TeV was to help to stabilise the Higgs mass against GUT scale quadratic radiative corrections. The combination of SUSY and GUTs has recently found some indirect experimental support due to the accurate measurement of the strong and electroweak couplings on the Z pole by LEP. These measurements are inconsistent with gauge coupling unification if a standard model desert is assumed, but are consistent with unification if a SUSY desert above the TeV scale is assumed [3].

In the first post-LEP analyses [3] the whole SUSY spectrum was either assumed to be degenerate at the scale M_{SUSY} , or smeared around this scale. In reality the SUSY partners may have a complicated spectrum, parametrised by a large number of soft SUSY-breaking parameters, which may spread over one or two orders of magnitude of masses. In order to reduce the number of independent soft SUSY-breaking parameters one may appeal to supergravity or superstring scenarios which involve the notion of SUSY breaking in a hidden sector coupled only gravitationally to our observable sector. By this means, in the minimal supersymmetric standard model (MSSM), one ends up with just four independent soft SUSY breaking parameters: m_0 , $M_{1/2}$, A_0 and B_0 corresponding to the universal soft scalar, gaugino, trilinear and bilinear couplings, respectively. Using these four parameters, together with the top quark Yukawa coupling which plays an important role in driving electroweak symmetry breaking [4], several groups have performed an RG analysis whose goal is to predict the SUSY and Higgs spectrum and then use this spectrum as the basis of a more reliable estimate of gauge coupling unification by running the gauge couplings through the various thresholds from the Z mass M_Z up to a unification scale M_X [4,5].

Apart from the constraints of gauge coupling unification and correct electroweak symmetry breaking, there are various other phenomenological and cosmological constraints which may be applied and recent studies have concluded that it is possible to satisfy all these constraints simultaneously [6].

Here we shall consider a slightly different low energy SUSY model, but one which is equally consistent with gauge coupling unification, namely the so-called next-to-minimal supersymmetric standard model (NMSSM) [7–9]. The basic idea of the NMSSM is to add just one extra gauge singlet superfield N to the spectrum of the MSSM, and to replace the μ -term in the MSSM superpotential with a purely cubic superpotential,

$$\mu H_1 H_2 \longrightarrow \lambda N H_1 H_2 - \frac{k}{3} N^3. \quad (1)$$

The motivation for this “minimal non-minimal” model is that it solves the so-called μ -problem of the MSSM [10] in the most direct way possible by eliminating the μ -term altogether, replacing its effect by the vacuum expectation value (VEV) $\langle N \rangle = x$, which may be naturally related to the usual Higgs VEVs $\langle H_i \rangle = \nu_i$. However there are other solutions to the μ -problem [10]. Also, the inclusion of singlets may cause the destabilisation of the hierarchy if there are strong couplings to super-heavy particles such as Higgs colour triplets [11]. Recently similar effects have been shown to result from non-renormalisable operators suppressed by powers of the Planck mass [12]. The dangerous non-renormalisable operators would require that gravity violate the Z_3 symmetry which is respected by the renormalisable operators of the theory. Our view is that since these effects are model-dependent the NMSSM is as well motivated as the MSSM and should be studied to the same level of approximation. Only by so doing may the two models be phenomenologically compared when (or if) Higgs bosons and SUSY particles are discovered.

In this Letter we present our first results of a GUT-scale RG analysis of the NMSSM, imposing simultaneously the constraints of correct electroweak symmetry breaking and coupling constant unification. In our analysis we shall drop all quark and lepton Yukawa couplings apart from that of the top quark h_t . We shall assume a soft SUSY breaking

potential which gives rise to three universal soft parameters at the M_X , namely m_0 , $M_{1/2}$, A_0 , mentioned above ¹. We shall use the two-loop gauge and Yukawa SUSY RG equations and one-loop soft SUSY RG equations to integrate from the GUT scale M_X to a low energy renormalisation scale Q . Below M_X , the three soft mass parameters evolve into 32 separate soft parameters, corresponding to 3 gaugino masses M_i , 11 trilinear couplings A_i (those of the MSSM plus A_λ and A_k) and 18 scalar masses m_i^2 (including the soft Higgs masses $m_{H_i}^2$, m_N^2). We assume no inter-generational mixing, and since we drop Yukawa couplings which are small compared to h_t , the first and second generation soft masses will run identically. The unification constraints are: $g_i^2(M_X) = g_X^2$, $\lambda(M_X) = \lambda_0$, $k(M_X) = k_0$, $h_t(M_X) = h_{t0}$, $M_i(M_X) = M_{1/2}$, $m_i^2(M_X) = m_0^2$, $A_i(M_X) = A_0$.

In practice we shall scale all dimensionful quantities by appropriate powers of $M_{1/2}$, and denote the resulting dimensionless quantities by a tilde. At the low energy $\overline{MS}$ scale Q we find the global minimum of the one-loop effective neutral Higgs potential, scaled by $M_{1/2}$, including loops of top quarks and stop squarks [13,14]. We only consider the neutral scalar Higgs potential, since there are simple analytical conditions which test for the presence of squark and slepton VEVs [8]. Although these are not guaranteed to prevent all possible charge or colour breaking minima as discussed by Gunion *et al* in reference [8], they are sufficient to avoid the most dangerous case of slepton VEVs, while a complete analysis of all possible colour breaking minima in the one loop effective potential is not feasible. We implement these conditions after running to an energy scale of order a typical slepton VEV. In addition we ensure that the mass squared of the charged Higgs remains positive in order to avoid breaking electromagnetism. The result of minimisation yields the scaled VEVs $\tilde{\nu}_i, \tilde{x}$, from which the condition $\nu = 174$ GeV fixes $M_{1/2}$. Given $M_{1/2}$ this enables all the soft parameters and the VEVs to be determined and, as described elsewhere [13,14], it is then straightforward to calculate the top and stop corrections to the Higgs boson mass spectrum.

¹ Note that the B parameter does not occur in the NMSSM since we have set $\mu = 0$.

The SUSY spectrum is calculated at tree-level using standard results [1], apart from squark masses which we calculate using the one-loop effective potential. There are a number of phenomenological constraints which will cut down the allowed regions of parameter space. We shall require that all sleptons and stops are heavier than 43 GeV and all charginos are heavier than 47 GeV. Charged Higgs bosons are required to be heavier than 45 GeV. Gluinos and squarks other than stops are required to be heavier than 100 GeV. The lightest neutralino is required to be the lightest SUSY particle. The lightest CP-even neutral Higgs boson h is required to satisfy $m_h/R_{ZZh}^2 \geq 60$ GeV, where m_h is the mass and R_{ZZh} is the ZZh coupling scaled by the standard model coupling. We shall require a large top quark mass, $m_t > 150$ GeV [15], which puts a strong restriction on the parameter space of this model. In our analysis we input the gauge couplings $g_1(M_Z)$ and $g_2(M_Z)$ and run them up through the 24 SUSY and Higgs thresholds to find M_X and g_X , which must of course be consistent with our original input values. By iterating this procedure we obtain solutions which satisfy both the requirements of correct electroweak symmetry breaking and coupling constant unification *simultaneously*. According to our procedure the parameters M_X and g_X are determined from $g_1(M_Z)$ and $g_2(M_Z)$, and so our input parameter set is: $\lambda_0, k_0, h_{t0}, \tilde{m}_0^2, \tilde{A}_0$, with the value of $M_{1/2}$ determined from the VEV. The physically relevant quantities $\alpha_s(M_Z) = g_3^2(M_Z)/4\pi$, m_t , $r = x/\nu$ and $\tan\beta = \nu_2/\nu_1$ are all outputs ².

A somewhat similar analysis to that described has been performed in the NMSSM by another group [16–18]. We have properly included the low energy threshold effects in our

²Our quoted values of m_t always refer to the one-loop physical pole mass $m_t = m_t^{pole} = m_t(m_t)[1 + \frac{4}{3\pi}\alpha_s(m_t)]$. Also, a word about our conventions is in order. In the convention of Eq.(1), we input positive values of λ_0, k_0 , and both positive and negative values of A_0 , and look for solutions with both positive and negative VEVs, except that we require $\nu_2 > 0$. Such solutions can always be re-interpreted in terms of purely positive VEVs using the three symmetries of the one-loop effective potential: (i) $\lambda \rightarrow -\lambda, k \rightarrow -k, x \rightarrow -x$, (ii) $\lambda \rightarrow -\lambda, \nu_1 \rightarrow -\nu_1$, (iii) $\nu_1 \rightarrow -\nu_1, \nu_2 \rightarrow -\nu_2$.

unification analysis, whereas in ref. [16–18] such effects were ignored. Since our choice of $\alpha_3(M_Z)$ and of M_X and g_X are determined by the requirements of consistent unification and thus vary with differing spectra, our approach is consequently much more computationally intensive since we have to run down the couplings, minimise the potential, calculate the spectrum, then run the couplings up through the thresholds, iterating this procedure many times in order to obtain a single point in parameter space which is consistent with unification and all the other constraints.

We initially considered a grid of 360,000 values of parameters in the ranges: $\lambda_0 = 0.01 - 2.0$, $k_0 = 0.01 - 2.0$, $h_{t0} = 0.5, 1, 2, 3$, $\tilde{m}_0 = 0.2 - 5.0$, $A_0/m_0 = -4$ to $+4$, then later investigated the phenomenologically interesting regions in more detail. For the acceptable regions of parameter space we find that $m_t > 150$ GeV is attainable for $k_0 < \lambda_0 < h_{t0}$, with $\lambda_0 < 1$ and $0.5 \lesssim h_{t0} \lesssim 3$, where the upper limit on h_{t0} is a requirement of perturbation theory. Although all values of h_{t0} in this range lead to consistent solutions with $|A_0/m_0| \approx 3 - 4$, for $h_{t0} \lesssim 0.5$ we also find solutions for smaller $|A_0/m_0|$, down to zero. However the cut on the top mass of $m_t > 150$ GeV excludes this region, and so we discuss it no further here. The successful values of $\tilde{m}_0$ vary across the whole range, but are correlated with h_{t0} and A_0/m_0 . To be specific, we find for $|A_0/m_0| \approx 3$ that $h_{t0} = 0.5, 1, 3$, is associated with $\tilde{m}_0 \sim 0.5 - 1, 1 - 2, 2 - 5$, while smaller values of $\tilde{m}_0$ can be obtained for larger $|A_0/m_0|$, although the maximum value of $|A_0/m_0|$ is about 4 (because of the slepton VEVs constraint). There are also correlations between λ_0 and k_0 at the unification scale, as discussed later. In the successful regions of parameter space we find $|\tan \beta| \sim 3 - 20$ (or larger, but our approximations break down here), while $|r|$ is virtually directly proportional to $M_{1/2}$, with $|r| \gg 1$ even for small $M_{1/2}$. Thus, as in ref. [16], we find that the allowed region of parameter space is characterised by small dimensionless couplings $|\lambda_0| < 1$, $|k_0| < 1$ and large singlet VEV $|x| > 1000$ GeV, corresponding to the approximate MSSM limit of the model [9].

To illustrate the correlation between λ_0 and k_0 , in Fig.1 we show contours of h_{t0} in the $\lambda_0 - k_0$ plane with $\tilde{m}_0 = 2$, $M_{1/2} = 500$ GeV and $|A_0/m_0| = 3$. Although we could have chosen other values of $M_{1/2}$, the qualitative features of Fig.1 would be unaltered, and the

value of k_0 would only change by a few per cent, since in this region the value of $M_{1/2}$ is a very sensitive function of λ_0 and k_0 . The $h_{t0} = 1, 2, 3$ contours correspond to $m_t \sim 175, 185, 190$ GeV, respectively, with $|\tan \beta|$ varying from 3-7 and $|r|$ from 100-30, from the lowest to the highest value of k_0 respectively. Values of k_0 beyond the ends of the plot are forbidden by the requirements of electroweak symmetry breaking, although the exact ranges of acceptable k_0 could be altered by varying our choice of A_0 and $\tilde{m}_0$ slightly. Similarly, m_t would be altered if we use a different $M_{1/2}$ primarily due to the resulting change in $\alpha_s(M_Z)$. As observed by other authors [3,4] we find that larger values of $M_{1/2}$ result in smaller values of $\alpha_s(M_Z)$. It should be noted that although changing the sign of A_0 leads to roughly the same output data with a change in the sign of r , this is only approximate, and in particular one sign of A_0 leads to a less restrictive slepton VEV constraint.

We find that, for many choices of our input parameters, there appears to be a certain minimum value of $M_{1/2}$ (recall that this is an output parameter). For example, if we impose a cut of $M_{1/2} \lesssim 150$ GeV, then $m_t > 150$ GeV is only possible for $h_{t0} \approx 1.5 - 3$, $|A_0/m_0| \approx 3$, $\tilde{m}_0 \approx 3 - 5$, corresponding to $m_t \sim 185 - 195$ GeV. The origin of the minimum value of $M_{1/2}$ is due to a different competing global minimum of the one-loop effective potential, which becomes preferred below a minimum $M_{1/2}$ value. This happens because the logarithm in the one-loop effective potential depends both on the renormalisation scale Q (which we have so far taken to be 150 GeV) and on $M_{1/2}$. To test the reliability of our results, we have investigated their Q -dependence. In doing this we have consistently used the same value of Q both in the RG running of masses and couplings and in the one-loop effective potential, since there is a significant cancellation between the effects of changing Q in these two places.

Although varying Q leads to very little change in the VEVs for any given minimum, it can alter the VEVs substantially by changing which of the minima is deepest (there are often minima with very different VEVs but with similar values of the potential). Given this behaviour, one must be very careful about drawing overly restrictive conclusions based on which of the various minima is preferred for a given region of parameter space. We find that reducing Q will typically lead to a reduction of the minimum value of $M_{1/2}$ in

those regions where small $M_{1/2}$ is not possible for $Q = 150$ GeV, but does not otherwise qualitatively change the behaviour. Note that the range of parameters $h_{t0} \approx 1.5 - 3$, $|A_0/m_0| \approx 3$, $\tilde{m}_0 \approx 3 - 5$ appears to be a “safe” range from the point of view of achieving small values of $M_{1/2} \lesssim 150$ GeV independently of the choice of Q . This dependence on Q is an inherent problem in this model because of the form of the effective potential which has several competing minima. In both our analysis and that of ref. [16–18] electroweak symmetry breaking has been analysed using the one-loop effective potential, including top quarks and stop squarks. In principle the Q dependence could be eliminated by including all particles in the effective potential, and possibly working beyond one-loop. Here we shall restrict ourselves to a discussion of the Q -dependence of our results.

We now consider two examples of the sort of Higgs and SUSY spectrum one might typically expect in the constrained NMSSM, the first with relatively large values of h_{t0} and $\tilde{m}_0$, and the second with relatively small values of h_{t0} and $\tilde{m}_0$. These two extreme cases span the complete range of spectra predicted by the constrained NMSSM, subject to the constraint of a large top mass $m_t > 150$ GeV.

In Fig.2 we plot the spectrum as a function of $M_{1/2}$ for the case $h_{t0} = 2$, $|A_0/m_0| = 3$, $\tilde{m}_0 = 5$, $\lambda_0 = 0.4$. With $Q = 150$ GeV we find that $M_{1/2}$ may go down to small values, which is not unexpected since these parameters are in the “safe” range $h_{t0} \approx 1.5 - 3$, $|A_0/m_0| \approx 3$, $\tilde{m}_0 \approx 3 - 5$, referred to above. Note that the experimental constraint that the charginos are heavier than 47 GeV implies that $M_{1/2} \gtrsim 70$ GeV in this case. For $M_{1/2} \approx 100(1000)$ GeV, which is controlled by choosing $k_0 = 0.275(0.300)$, we find $|\tan\beta| \approx 6(8)$, $|r| \approx 13(120)$, $\alpha_s(M_Z) \approx 0.121(112)$, $M_X = 2.1(0.99) \times 10^{16}$ GeV, $g_X = 0.71(0.69)$. The lightest CP-even Higgs boson has standard model-like couplings ($R_{ZZh} > 0.99$ everywhere) and for $M_{1/2} \lesssim 100$ GeV is in the LEP2 range, as are the lighter chargino and neutralinos which have a much stronger $M_{1/2}$ mass dependence. The top quark mass ranges from $m_t = 193 - 184$ GeV, being smaller for larger $M_{1/2}$ due to $\alpha_s(M_Z)$ being consequently smaller. For $M_{1/2} \lesssim 100$ GeV, the lightest stop and gluino are not too much heavier than the top quark, although the remaining sparticles and Higgs bosons are significantly heavier than the top quark.

In Fig.3 we plot the spectrum as a function of $M_{1/2}$ for the case $h_{t0} = 0.5$, $|A_0/m_0| = 4$, $\tilde{m}_0 = 0.5$, $\lambda_0 = 0.1$. These parameters are outside the “safe” range $h_{t0} \approx 1.5 - 3$, $|A_0/m_0| \approx 3$, $\tilde{m}_0 \approx 3 - 5$, in which small $M_{1/2}$ can be achieved independently of the choice of the renormalisation scale Q , and so we plot the spectrum for two choices of Q . The main effect of changing Q is to change the value of $M_{1/2}$ at which the data cuts out. For $Q = 150(25)$ GeV, we find the minimum values $M_{1/2} = 300(125)$ GeV corresponding to $m_0 = 150(62.5)$ GeV. As in Fig.2, the lightest CP-even Higgs boson has standard model-like couplings, and for a given $M_{1/2}$ is even lighter than in Fig.2. For the smaller $M_{1/2}$ values which we can obtain with $Q = 25$ GeV the lighter chargino and neutralinos may be in the LEP2 range. Unlike Fig.2, the left-handed sleptons are now much lighter (due to the smaller value $\tilde{m}_0 = 0.5$) while the lighter stop is much heavier (due to the smaller value $h_{t0} = 0.5$). The top quark mass has a maximum value of $m_t = 175$ GeV for $M_{1/2} = 125$ GeV and here $|\tan\beta| = 3.4$. The gluino in Fig.3 is now the heaviest sparticle, whereas in Fig.2 it was one of the lighter ones. In general the Higgs and sparticle masses in Fig.3 are focussed into a narrower band of masses than in Fig.2, which is a simple result of having $\tilde{m}_0 = 0.5$ rather than $\tilde{m}_0 = 5$.

Finally it is worth comparing our spectra to the spectra discussed in a paper which appeared just as this present article was being finalised [18]. In this most recent analysis the Higgs and SUSY spectrum was presented as a series of scatter plots for masses and couplings. Most of this data and all of ours corresponds to one of the CP-even Higgs bosons being almost pure gauge singlet. Such a decoupled Higgs boson might be expected since the constrained NMSSM is close to the MSSM limit. In the analysis of ref. [18] the decoupled Higgs boson may have a mass either less than or greater than the lighter of the other two CP-even Higgs bosons and when the would-be decoupled Higgs is close in mass to the lighter physical Higgs, strong mixing can occur, leading to two weakly coupled Higgs bosons of the kind discussed in ref. [14]. However, given the range of parameters considered in this paper, we find that the decoupled CP-even Higgs boson is always substantially heavier than the lighter of the two physical CP-even Higgs bosons. Similarly the CP-odd Higgs bosons

are much heavier than the lightest CP-even Higgs boson. The reason for this difference is simply that in ref. [18] the range of parameters considered exceeds the range considered in this paper. It turns out ³ that in order to bring down the mass of the CP-even singlet sufficiently one requires $\tilde{m}_0 \ll 0.2$, $\lambda_0 < 0.01$ and $k_0 \ll \lambda_0$, corresponding to extremely large values of $r \gg 100$. We have checked that, in this region of parameter space, the singlet CP-even Higgs boson does indeed become much lighter, leading to the strong mixing effect mentioned above. However, for the range of parameters considered in the present paper, a standard model-like Higgs boson with a mass in the range 70-140 GeV is preferred.

Figure 1: A contour plot showing allowed values of λ_0 and k_0 for given values of $h_{t0} = 1, 2, 3$ (going from left to right) in the λ_0 - k_0 plane, corresponding to $M_{1/2} = 500$ GeV, $\tilde{m}_0 = 2$ with $|A_0/m_0| = 3$.

Figure 2: Masses of particles as a function of $M_{1/2}$. The input parameters are $h_{t0} = 2$, $|A_0/m_0| = 3$, $\tilde{m}_0 = 5$, $\lambda_0 = 0.4$, $k_0 = 0.275 - 0.3$. We use $Q = 150$ GeV. Neutralinos (solid lines), charginos (dot-dashed lines), CP-even Higgs (short dashed lines), lighter stop and top quark (both dotted lines), left-handed sleptons (long dashed lines), and gluino (quadruple dashed lines) are displayed. One of the CP-odd Higgs and the charged Higgs bosons (not shown) are roughly degenerate with heavier CP-even Higgs bosons. The remaining CP-odd Higgs boson (not shown) is heavier than the heaviest neutralino. The lightest CP-even Higgs (which has standard model-like couplings), lighter chargino and lightest two neutralinos are all in the LEP2 range for $M_{1/2} \lesssim 100$ GeV.

Figure 3: Masses of particles as a function of $M_{1/2}$. The input parameters are $h_{t0} = 0.5$, $|A_0/m_0| = 4$, $\tilde{m}_0 = 0.5$, $\lambda_0 = 0.1$, $k_0 = 0.07 - 0.13$. In addition to using $Q = 150$ GeV, as in Fig.2, we also show results for $Q = 25$ GeV, corresponding to minimum values of $M_{1/2} = 300$ GeV and $M_{1/2} = 125$ GeV, respectively. Neutralinos (solid lines), charginos (dot-dashed lines), CP-even Higgs (short dashed lines), lighter stop and top quark (both dotted lines), left-handed sleptons (long dashed lines), and gluino (quadruple dashed lines) are displayed. One of the CP-odd Higgs (not shown) is roughly degenerate with the second heaviest CP-even Higgs boson. The remaining CP-odd Higgs boson (not shown) is roughly equal to the lighter stop mass. The lightest CP-even Higgs (which has standard model-like couplings as in Fig.2) has a mass $\lesssim 100$ GeV.
